The Structure and Variability of Extended S II 1256Å Emission Near Io

R. Carey Woodward, Jr.,[1,6] Fred Roesler,[1,6] Ronald Oliversen,[2,6] William Smyth,[3] H. Warren Moos,[4] Fran Bagenal[5]

Introduction

Since the first Space Telescope Imaging Spectrograph (STIS) observations of Io in 1997 [*Roesler et al.*, 1999], 32 spectrally dispersed STIS images of Io containing the S II 1256Å line have been obtained during eight "visits" or observing sequences (table 1). Each image consists of $2'' \times 25''$ rectangles containing Io, which includes emission out to 15–40 Io radii from the moon, replicated for each emission line present (figure 1). Previous work has concentrated on the neutral S and O emission from Io, primarily on and near Io's disk; here we examine the radial structure of the extended S II 1256Å emission. (In the thirty images studied here, the low dispersion of the G140L grating—0.584Å/pixel—makes it difficult to distinguish between S II 1256Å and possible S I 1251Å emission; the two G140M images, at 0.053Å/pixel, show that no detectable S I 1251Å emission exists.)

Reduction & Analysis

In addition to the problem of overlapping lines common to all spectral features, this analysis is complicated by two factors that collectively are unique to extended ion emission: the presence of background plamsa torus emission, and the existence of an unexpected and poorly-understood "blotch" of dark current in the FUV MAMA detector, which can simulate a broad wings in an emission line.

The "dark glow" in the STIS FUV MAMA detector consists of a uniform dark current, often in excess of the design rate of $\sim 7\times10^{-6}$ counts/sec, and a "blotch" which is peaked in the upper left quadrant of the MAMA. *Landsman* [1998] describes this dark current, presents a "superdark" image consisting of summed dark current from 288 dark images totalling 397,440 seconds of integration, and derives an approximate dependence of global dark rate on the STIS low voltage power supply temperature (LVPST). This LVPST relationship proved to have too much scatter to be useful for our work; we therefore defined a dark function consisting of an adjustable uniform dark current added to the smoothed "superdark" with an adjustable scaling factor, and created a synthetic dark image for each data image by fitting (in the least-square sense) this dark function to the data in the emission-free area of the G140L images between S I 1479Å and S I 1667Å, avoiding Io's neighborhood and the slit image's occulting bar. (Other emission-free areas were used in the G140M images.) This dark function fit the dark areas well and unambiguously, and varied with LVPST in the same manner of (and with the same scatter as) *Landsman* [1998] (figure 2).

We then reduced the images and the synthetic darks using the standard CALSTIS pipeline, removed areas contaminated by other lines, averaged the pixels over $0.1\,R_{Io}$ radial bins in 60° wedges centered on the long slit direction, and finally subtracted the darks from the data (figure 3). We created model slit images using IPTGEM [*Woodward and Smyth*, 1994], calculating each component of the S II 1256Å triplet and convolving them appropriately, and calculated radial profiles from them in the same way. (We did not attempt to deconvolve the data, as this would be difficult and would make little difference outside of $\sim$2–3 R_{Io}.) These model profiles were almost all smaller than the data, so we scaled them to fit the data at $r > 10R_{Io}$, with an adjustable offset.

Results

The results are tabulated in table 1 and plotted in figure 3; the scaling factor is 2–3 in most cases, but could be as high as 6. These scaled models fit the data well outside of $10\,R_{Io}$, but unsurprisingly do not fit the near-Io emission. We believe that a factor of 2–3 is a result of antiquated atomic emission data, but that the rest represents genuine variation in the torus. Of particular interest to us was a large, highly asymmetric brightening in the extended S II 1256Å emission on 14 October 1997, correlated with brightenings in neutral O and S UV lines in the same STIS data and with [O I] 6300Å observed from the ground [*Woodward et al.*, 2000]. This brightening is now seen to be unique in the full dataset, and moreover to be consistent with a > 2-fold brightening of the underlying torus. The near-Io excess emission also increases, but is much more symmetric than was previously believed.

Finally, we chose an image in which the dark current was low and uniform, and the background torus contribution was small and linear (and therefore contributed minimally to the profile shape), subtracted the (scaled) torus model from the data, and compared the the result to the S I 1479Å emission from the same image (figure 4). Contrary to our expectations based on the appearance of the raw data, the two are indistingiushable.

Summary

- Thirty spectrally resolved far-UV images of Io's neighborhood have been studied in the S II 1256Å line. The STIS FUV MAMA "dark glow" proved a significant contaminant in some images; a special reduction technique was developed to mitigate this problem.
- For most images, the 1256Å emission more that $\sim 10\,R_{Io}$ can be characterized by the predicted plasma torus emission, based on Voyager data, with an empirically chosen scaling factor and offset. The scaling factor ranges from 0–6, but is usually 2–3, and is consistent with the variable nature of the plasma torus.
- In particular, the anomalous brightening of this line on 1997/10/14 is consistent with a > 2-fold brightening of the underlying torus. Near-Io emission also jumps, suggesting local S^+ was "lit up" by enhanced torus electron density.
- In at least one image, the 1256Å emission profile not attributable to the "dark glow," a constant background, or the plasma torus, is indistinguishable from the S I 1479Å emission.

Date	Time	Root name	LVPST	ζ	λ_{III}	ϕ_{Io}	TF

Table 1: *Observational and reduction parameters. Date and time are observation midpoints (UT). LVPST is the STIS Low Voltage Power Supply Temperature (Kelvins). ζ is the angle (°) of the line of sight with respect to terrestrial antisunward. λ_{III} is Io's System III longitude (°). ϕ_{Io} is Io's phase angle; 0° is superior conjunction with Jupiter. TF is the torus model scaling factor that best fits the data. [M] marks G140M (medium spectral resolution) data; others are G140L.*

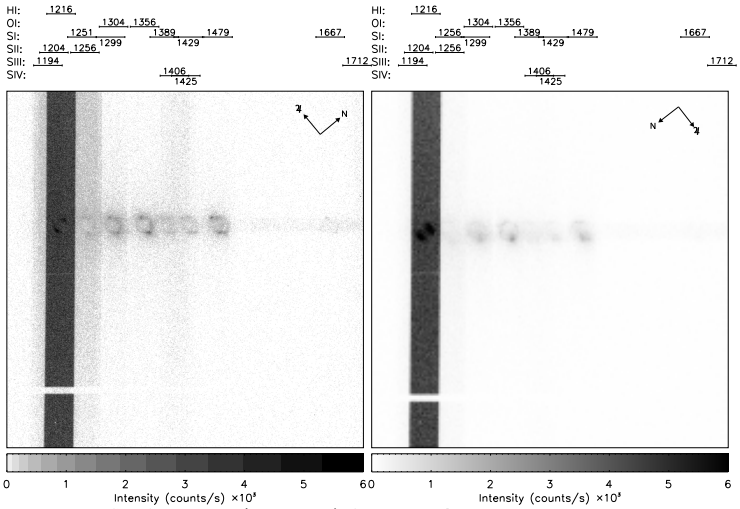

Figure 1: *STIS images (raw data) from the first two visits. Each image is* 1024×1024 *pixels, each* $0.0244''$ *square on the sky plane, with 0.584 Å/pixel dispersion convolved with the spatial information horizontally; thus, for each emission wavelength, a "slit image" appears at a different (but potentially overlapping) position on the detector. Positions of slit images for expected emission wavelengths are shown above the image. The emission of interest in this work is S II 1256Å, next to (and partially overlapping) the bright Lyman-α slit image. The small circular features are emission near Io's limb.*
